#### Abstract

Packed beds are used in many process industries (e.g. Adsorption, Absorption, Distillation, and Filtration).

This research involved the study of packed bed properties and tests it in theoretical and experimental methods.

The packing consist of four sizes of glass spheres and their diameters are: $\mathrm{d} 1=10.6 \mathrm{~mm}, \mathrm{~d} 2=14.97 \mathrm{~mm}, \mathrm{~d} 3=20.89 \mathrm{~m}, \mathrm{~d} 4=25.84 \mathrm{~mm}$.

The theoretical method was given by Latif involve evaluating the diameter of the pores, mean pore diameter, and the probability due to number, surface area, length, and volume .the results obtained using software programs (Q.BASIC, EXCEL) and these results shows that the probability of finding pore size is different for each distributions.

The experimental work was by making a packed bed with different composition and layers but the same diameters used in theoretical methods and weigh the impurities before entering the packed bed and after leaving it to find the percent output .Three sizes of impurities were used and its diameters are: $1.2-3.3 \mathrm{~mm}, 4.2 \mathrm{~mm}$, and 6 mm .

Results obtained from the experimental work showed that the percent output of impurities decreased with increasing the number of layers; and also decreased with increasing the size of impurities for each value of number percent of spheres. Experimental results related with the theoretical results in order to find the relation between mean pore diameter and percent output of impurities for each bed.

Definition
$\mathbf{a}_{\mathbf{k}} \quad$ Ratio between diameter of small and large particle.
$\mathbf{a}_{\mathrm{m}} \quad$ Ratio between diameter of medium and large particle.
$\mathbf{A g}_{\mathbf{g}} \quad$ Area function of large spheres.
$\mathbf{A}_{\mathbf{K}} \quad$ Area function of small spheres.
$\mathbf{A}_{\mathbf{m}} \quad$ Area function of medium spheres.
d Particle diameter. mm
dc Diameter of the pores. mm
$\mathbf{d c}_{\mathbf{1}}$ Pore diameter of three different sizes of diameter. mm
$\mathbf{d c}_{2}$ Pore diameter of two equal and one different mm
size of diameter.
$\mathbf{d c}_{3} \quad$ Pore diameter of three equal sizes of diameter. mm
$\mathbf{d c}_{\mathbf{m}}$ Mean pore diameter mm
$\mathbf{d c}_{\mathbf{m}} \mathbf{a}$ Mean pore diameter due to area. mm
$\mathbf{d c}_{\mathbf{m}} \mathbf{l}$ Mean pore diameter due to length. mm
$\mathbf{d c}_{\mathbf{m}} \mathbf{n}$ Mean pore diameter due to number. mm
$\mathbf{d c}_{\mathbf{m}} \mathbf{v}$ Mean pore diameter due to volume. mm
$\mathbf{d}_{\mathbf{g}}$ Large particle diameter. mm
$\mathbf{d}_{\mathbf{K}}$ Small particle diameter. mm
$\mathbf{d}_{\mathbf{m}}$ Medium particle diameter. mm
$K_{1}$ to $K_{5}$ constants
$\mathbf{L}_{\mathbf{g}} \quad$ Length function of large spheres.
$\mathbf{L}_{\mathbf{k}} \quad$ Length function of small spheres.
$\mathbf{L}_{\mathbf{m}} \quad$ Length function of medium spheres.
n Number of repetition.
$\mathbf{n}_{\mathrm{g}} \quad$ Number of repetitions for large particles.
$\mathbf{n}_{\mathrm{K}} \quad$ Number of repetitions for small particles.
$\mathbf{n}_{\mathrm{m}} \quad$ Number of repetitions for medium particles.
$\mathbf{N}_{\mathrm{g}} \quad$ Number function of large spheres.
$\mathbf{N}_{\mathbf{k}} \quad$ Number function of small spheres.
$\mathbf{N}_{\mathbf{m}} \quad$ Number function of medium spheres.
$\mathbf{P}_{\mathbf{i}} \quad$ Probability of finding the pores.
$\mathbf{P}_{\mathbf{r}} \quad$ Probability for diameters.
$\mathbf{P}_{\mathrm{ra}} \quad$ Probability of diameters due to area.
$\mathbf{P}_{\mathrm{rl}} \quad$ Probability of diameters due to length.
$\mathbf{P}_{\mathrm{rn}} \quad$ Probability of diameters due to number.
$\mathbf{P}_{\mathrm{rv}} \quad$ Probability of diameters due to volume.
$\mathbf{r}$ Type of distribution.
$\mathbf{r}_{\mathbf{g}} \quad$ Type of distribution for large particles.
$\mathbf{r}_{K} \quad$ Type of distribution for small particles.
$\mathbf{r}_{\mathrm{m}} \quad$ Type of distribution for medium particles.
$\mathbf{V g}_{\mathbf{g}} \quad$ Volume function of large spheres.
$\mathbf{V}_{\mathbf{k}} \quad$ Volume function of small spheres.
$\mathbf{V}_{\mathbf{m}} \quad$ Volume function of medium spheres.

## Chapter One

## Introduction

### 1.1. Introduction

Many materials (ex. soil, sand, packed catalyst bed) consist of a large number of particles or fibers packed bed closely together .In between the solid particles or fibers there is open space called "pores"[1].

Pores are void spaces which must be distributed less frequently through the material if the latter is to be called "porous". Extremely small voids in a solid are called "molecular interstices", very large ones are called "Caverns". "porous" are void space intermediate between caverns and molecular interstices; the limitation of their size is therefore intuitive and rather indefinite [2].

A packing of particles is an assemblage of particles and is widely encountered in many industries. Pore size is known to be the simplest and most accessible parameter in characterizing particle packing. Particle characteristics affect porosity mainly via three factors:

- Dimensionless particle size distribution.
- Particle shape.
- Absolute particle size.

Giving various packing systems from the simplest spherical particle packing to the complicated system involving fine and non- spherical powders [3].

Porous materials occur in great variety, both in nature and industry .living organisms are all Porous; their life functions would not be possible without porous in them .pores make breathing possible as well as the circulation of natural fluids in both plant and animal life [4].

In the inanimate world porous structures are just as widespread and important. Soil is porous and so are most natural rocks, to a varying degree. Graphite, mica, sand stone, and limestone, fibrous aggregates such as cloth, felt, filter paper, and catalytic particles containing extremely fine micro pores are just a few examples [4].

Ground water, petroleum, and natural gas are among the important substances that are contained in the pore spaces provided by various geological functions. Among industrial products, porous materials are again numerous and of great practical value. Materials of construction such as ceramics, concrete, and timber are porous [4].

In addition, porous materials play an important role in many process industries as adsorbents, such as silica gel, active charcoal, zeolites-molecular sieves, a large variety of contact catalysts, and filters. Electrodes in batteries and electrolysis plants are often porous. Many commercials products are granular or porous, and technology of drying such as materials has to consider their porous nature. The pore structure of ores is important in process metallurgy [4].

The variety of porous materials and their spherical significance, along with the shapes, sizes, and nature of the pores is so great, that no comprehensive treatment of the pore structure analysis has ever been attempted [4].

The pores in a porous system may be interconnected or none interconnected. Flow of interstitial fluid is possible only if at least part of the pore space is interconnected. The interconnected part of the pore system is called the effective pore space of the porous medium [2].

Pore spaces have been divided according to whether they are ordered, or disordered; and also according to whether they are dispersed (as in beds of particles) or connected [2].

Pore space models are used to obtain values for the transport coefficient (effective diffusion coefficient permeability) and -when applicable - the driving force (capillary potential) in the transport equation. These models and this approach have to be distinguished from:-

* Models used in simulating particle packing.
* Models used in determining the so-called pore size distribution (suction technique, mercury porosimetry).
* Analytic calculation of the transport coefficient.
* Overall description of the transport phenomena. (In which the microscopic pore space structure is not accounted for.) [5].

In this research we will give a description of pores using spherical particles which will pass through expected pores, and evaluate the probability of the pore diameter due to volume, surface area, number, and length and relate the experimental results with the theoretical method for calculation.

## Chapter Two

## Literature Survey

### 2.1. Descriptions and Physical Properties of Porous Media

Transport in heterogeneous and disordered media has important applications in many fields of science including composite materials, rheology, geophysics, polymer physics, statistical physics, chemical physics, colloid science, petroleum exploration and technology, and biotechnology. Progress in the field of heterogeneous media was, until recently, hampered by the difficulties involved in characterizing the complex random microstructure. The problem consists in characterizing the microstructures quantitatively in such a way that the characterization can be used to predict physical transport quantities such as permeability, conductivity or elastic constants [6].

A general and unified methodology was developed to characterize disordered heterogeneous materials quantitatively. This methodology was given the name local porosity theory because it focuses on local fluctuations of porosity and other geometrical descriptors. It allows a quantitative transition from microscopic to macroscopic scales in porous media [6].

A particularly important subclass of disordered heterogeneous materials is porous media. For porous media, the prediction of multiphase fluid flow has remained largely impossible despite many years of research in academia and industry. Solutions to this problem would be of great importance for many applications (e.g. prediction of groundwater flow, chemical reactions in
catalysts, and flow through gels, granular media, textiles, constructions materials, filtration technology, hydrocarbon production or in situ remediation of contamination areas) $[7,8,9,10]$.

A porous medium consists of a connected 3-dimensional solid matrix with a highly ramified network of pores and pore throats in which fluids may flow. Porous media are often characterized in terms of "pore size distributions" but this does not provide a sufficient description for the calculation of important physical properties such as permeability [11].

A variety of models for the pore space geometry of porous media have been developed. However, simple models that can be used to calculate macroscopic physical properties have not been developed [11].

A considerable effort has been invested in making transparent models of porous media by using transparent solid materials for the matrix and fluids of the same index of refraction. Vidar Frette has been a driving force in the development of the three-dimensional transparent models and has used the technique to study many interesting interface-structures arising in two-fluid displacement in three-dimensional experiments [11].

### 2.2. Theory of Packing of Spheres and Natural Materials

In order to establish a correlation between grain size and pore size of an unconsolidated porous medium, one has to know something about the packing of the grains as well as about their shape [12].

For even the size of the grain (i.e. the largest diameter) is known, the shape is still not determined. The grains that pass through a certain sievemash and do not pass through another slightly smaller one are not necessarily all identical, owing to the irregularity of shape [12].

The first study of the models of packing of spheres and the porosity calculated therefore appears to have been under taken by Slickter (1899).since then the theory has been reviewed, refined, and extended by Smith, Foote and Busang (1929), Graton and Fraser (1935) fig.2.1, Manegold (1937), Manegold and Solf (1939), Hrubisek (1941), and others sited in [13, 14].

Fig.2.1. Rhombohedral packing of spheres.

Natural materials are composed of grains whose shape may deviate appreciably from that of spheres. Moreover, it will often be found that the grains are somewhat cemented together without being fully consolidated, but it would still be desirable to apply some correlations between " grain size" and pore size distribution and other characteristics of the porous medium, such as specific area. Furthermore, the size of the grains will seldom be very uniform. Non-uniformity in size will, in general, permit the smaller particles to fill the spaces between the larger ones and thus appreciably reduce porosity. Contrariwise, angularity of the particles permits bridging with a resulting increase of porosity [15, 16, 17].

Theoretical and experimental studies of the effect of grain size on pore size have been conducted by Tickell, Mechem and McCurdy (1933), Nissan (1938), Cloud (1941), Rosenfeld (1949), Griffiths (1952), and Gaither (1953) sited in [18, 19, 20, 21].

### 2.3. Pore Size, Shape and Distribution

There are three basic pore models exist: [22]

1. Cylindrical pores, circular in cross section.
2. Ink-bottle pores having a narrow neck and wide body.
3. Slit-shaped pores with parallel plates.

Pore size distribution is the secondary parameter. This could be measured by the method of mercury porosimetry [22].

Mercury porosimetry method is most widely used in the measurement of pore-size distribution. In the mercury intrusion porosimetry method, a
cylindrical pore model is assumed, and the size of pores is principally calculated using the Washburn equation:

## $D=14(\cos \alpha / p)$

Where D is the apparent diameter of the pore being intruded, $\alpha$ is the contact angle between mercury and the material, and P is the absolute pressure causing the intrusion. This equation can be used to convert pressure to pore diameter. The pore-size distribution can be determined by measuring the volume of mercury intruded into the pores as a function of pressure [23].

More direct methods using the principles of X-ray scattering have been employed (Brusset, 1948; Ritter and Erich, 1948; Shull, Elkin and Roess, 1948; Avgul etal. 1951; Clark and Liu, 1957) [2].

Another method is to break down porous medium by crashing it more and more finely. At each stage of crushing the porosity can be measured, which turns permits evaluation of the pore size distribution as the larger pores, are progressively destroyed (Gilchrist and Taylor, 1951) [2].

But the most modern technique to measure pore size distribution is the TRI/Autoporosimeter.

The TRI/Autoporosimeter is a unique, computer-controlled, precision instrument with user-friendly hardware and software. It measures pore size distribution, pore volume distribution, and numerous other characteristics of porous materials in the pore radii range of 1 to 1,000 microns in a nondestructive manner [24].

### 2.4.Pore Size Measurement using new NIST Traceable Micro Sphere Standards

Pore size measurement has been traditionally performed by the Bubble Point measurement where by the maximum aperture size present can be related to the pressure at which a bubble appears on the top side of a wetted filter medium pressurized [25].

An alternative method is the so-called 'Challenge test'. In this method standard test dusts or glass beads are presented to a filter medium and the size distribution in the downstream flow analyzed. This method gives a more absolute measurement of pore size because it measures real particles but, because the size distributions involved are often broad, there is a significant uncertainty in the measurement of the largest particles passing the filter medium [26].

Particle shape can also affect the penetration of the filter media by the challenging particles, irregular particles tending to lock into the tortuous pathways through the filter media. A simple example is the comparison of spheres and discs passing various filter media, figure 2.2. The optimum particles for a challenge test are therefore spherical, narrow size distribution micro spheres [27].

Fig. 2.2. Particle shape and aperture shape affect filter efficiency

The complex structures produced from the latest weaving technology make traditional testing methods such bubble point measurements and challenge test methods less reliable. Potential users of filter media are therefore demanding more accurate methods of filter pore size measurement and this requires a different approach and technical understanding of filtration efficiency. It will describe the preparation and use of narrow particle size distribution glass micro sphere standards in measuring the pore sizes of some of the latest high performance filter media [28, 29].

### 2.4.1Pore size measurement by using sonic shifting:-

Measuring the pore size of micro spheres effectively through the often tortuous path in the complex filter structure is difficult .This problem has been solved by using a Sonic sifting device that fluidizes the micro spheres rather than shake the filter as in traditional sieve shakers. The pore size measured is approximately $97 \%$ of the maximum particle passing the medium when
measured by microscopy, or effectively cut point or retention quality of the filter medium [29].

### 2.4.2 Pore size measurement using an ultrasonic wet system:-

Although the Gilson Sonic shifter can measure particles on an Electroformed sieve down to 5 mm , the restricted flow through filter media of a similar pore size makes fluidization almost impossible and a wet, ultrasonic method must be used. The apparatus employed was a simple split filter holder on a Buchner flask, an ultrasonically dispersed dilute suspension of an appropriate filter standard was then drawn through the filter under test by vacuum. The particle size before and after filtration was analyzed by microscope and image analysis [29].

### 2.5. Applications to Seperation [30]

### 2.5.1 Description of Elementary Mechanisms

Consider the inventory of all parameter which describes the elementary process of clogging and décolletage, i.e., the retention sites fig.2.3, the retention force exerted on the particles retained in these sites, the capture mechanisms which bring the particles into contact with the sites, as well as the décolletage processes of retained particles.

- Constriction sites: the particle can not penetrate into pore of smaller size than its own.
- Retention sites: it is possible to distinguish several retention sites.
- Surface sites: the particles stops and is retained on the surface of porous bed grain.
- Crevice sites: the particle becomes wedged between the two convex surfaces of two grains.
- Cavern sites: the particle is retained in a sheltered area, a small packed formed by several grains.

Constriction sites

Cavern sites

Fig. 2.3. Several retention sites

### 2.5.2 Retention Force

They include:

- Friction Force: A particle wedged in a crevice may have been slightly deformed then when stopped, and may remain in place by friction.
- Surface Forces: these include the Van deer Val forces, which are always attractive, and the electrical forces (electrostatic or electro kinetic) which are either attractive or repulsive according to the physiochemical conditions of the suspension.
- Chemical forces: in the case of colloidal particles or other particular cases actual chemical bonding may occur.

### 2.5.3 Capture Processes

These are:

- Sedimentation: if the particle have a density different from that liquid, they are subjected to gravity and their velocity no longer is that of the fluid, thus by sedimentation they can meet the filter medium.
- Inertia: still owing to their apparent weight, the particles can not follow the same trajectories as the fluid, they deviate from the stream lines (when the directions of the trajectories change suddenly) and can be brought into contact with the bed grains.
- Hydrodynamic effect: owing to the non-uniform shear fluid and the nonsphericity of particular, hydrodynamic effect may occur; these effects cause a lateral migration of suspended particles which may be brought into contact in this way with retention sites.
- Direct interception: even with exactly the same density as the fluid, the particles would not be able, owing to their size, to follow the smallest tortuosities of the streamline of the carrier fluid and they will thus collide with the walls of the convergent areas of the pores.
- Diffusion by Brownian motion: the particles diffuse and can reach areas which are not normally irrigated by the suspension, and they are retained there.

### 2.5.4 Decollitage Processes

It is necessary to distinguish between the spontaneous Décolletage due to the normal flow of suspension through the clogged bed, and the Décolletage caused by the operator who suddenly changes the flow conditions.

Spontaneous décolletage may occur if local variations in pressure or flow rate change the flow in the neighborhood of retained particles or if moving particles collides with retained particles

Provoked décolletage results from impulses i.e. from sudden variations in pressure or flow rate in the whole bed caused by the operator or by reversal of the flow direction

The processes of spontaneous or provoked décolletage are similar, but the extent of the first is local, whereas the second occurs every where in the whole bed

### 2.5.5 Significance of Direct Interception

Even if particles have the same density as fluid, they meet the filter medium when streamlines they follow become nearer than $\mathrm{d} / 2$ for the grain surfaces; this process occurs in the constrictions and flow-past obstacles fig. 2.4. The particles brought into contact with the filter medium will stop if there are some available retention sites.

Fig. 2.4. Direct interception.

### 2.5.6 Elementary Mechanisms

Retention sites according to delachambre and sakthivadivel; particles follow the streamlines but are stopped in the passageways to narrow for passage (crevices and constriction).the resulting deposits continuously reduced the free passage and eventually causes blocking and filling up of settle by gravity on the grain tops on the horizontal pore services and thus narrow or block the channels[31].

The various studies about flow of suspension through porous media allow the following conclusions:

1. The possible elementary mechanism of deep filtration is known and they could be brought in evidence. However, it is always difficult to evaluate accurately their significance in any system. Therefore, experimental studies are needed before any filtration.
2. Two theoretical filtration types may be defined:

- A mechanical deep filtration for large particles (over30 $\mu$ ); for them, volume phenomena prevail and spontaneous décolletage is improbable.
- A physiochemical deep filtration for small particles (approx. $1 \mu$ ); for them, surface effects prevail and spontaneous décolletage may occur in case of sudden variations of flow rate or pressure.
- Typical deep filtration is performed for mean particles of intermediary size; thus, volume phenomena and surface effects have the same order of magnitude.

3. The fluid pressure drop through the porous medium increase with retention [31].

### 2.6. Models and Equations for the Calculation of Pore Diameter

There are three models which are based on an experimentally accessible quantitative characterization the pore space geometry [5].

One-dimensional models entail that transport is possible in one direction only as in Fig. 2.5; two dimensional models permit transport in a plane containing the microscopic transport direction as in Fig 2.6 and, three dimensional models permit transport also in plane perpendicular on the microscopic transport direction as in Fig. 2.7[5].

Packing of the packed bed which will represent the pore medium, and impurities have been represented as spherical particles by Latif (1981) as shown in fig.2.8. [32]

A mathematical procedure will be use which helps to study the motion of impurities, and packed bed particles is suggested. In this work we use the same procedure to find the pore size of a packed bed consisting of spheres and impurities as small spherical particles.

Fig. 2.5. Elements of pore space models with One-dimensional connectivity

Fig．2．6．Elements of pore space models with
Two－dimensional connectivity

Fig. 2.7. Elements of pore space models with Three-dimensional connectivity

Filtrate

- Impurities

O Sphere glass

Fig. 2.8. Filter Aids model

The calculation procedure is as follows:

1. The diameter of the spheres $\left(\mathrm{d}_{C_{1}}\right)$ which may be able to pass through the pore, as shown in Fig.2.9.1, which represent the general case [32].

$$
d_{C 1}=\frac{k_{4}-\left(k_{4}^{2}-4 k_{5}\right)^{0.5}}{2} \times d_{g}
$$

Where:

$$
\begin{gathered}
k_{1}=\left[\frac{\left(a_{m}+1\right)}{\left(a_{m}-1\right)}\right]^{2} \\
k_{3}=\left(a_{k}^{2}+a_{k} k_{2}\right)^{0.5}-a_{k} \\
k_{5}=k_{3}^{2} \times k_{1} \\
\left(a_{m}+1\right) \\
a_{k}=\frac{d_{k}}{d_{g}} \quad k_{4}=\left(k_{2}+2 k_{3}\right) \times k_{1} \\
\quad a_{m}=\frac{d_{m}}{d_{g}} \quad(=1)
\end{gathered}
$$

2. The diameter $\left(\mathrm{d}_{C 2}\right)$ as shown in Fig. 2.9.2 and 2.9.3 may be calculated by equation 2.2.a and equation 2.2.b for case a and b respectively [32].

$$
\begin{align*}
& d_{C 2}=\frac{\left[\left(2 a_{k}+a_{k}^{2}\right)^{0.5}-a_{k}\right]^{2}}{2+2\left[\left(2 a_{k}+a_{k}^{2}\right)^{0.5}-a_{k}\right]} \times d_{g} \\
& d_{C 2}=\frac{\left[\left(2 / a_{k}+a_{k}^{-2}\right)^{0.5}-a_{k}^{-1}\right]^{2}}{2+2\left[\left(2 / a_{k}+a_{k}^{-1}\right)^{0.5}-a_{k}{ }^{-1}\right]} \times d_{k}
\end{align*}
$$

Where:

$$
a_{k}=\frac{d_{k}}{d_{g}}
$$

3. The diameter $\left(\mathrm{d}_{C 3}\right)$ can be calculated by the equation written below when $\mathrm{dk}=\mathrm{dm}=\mathrm{dg}$ we have, see Fig. 2.9.4.[32]

$$
d_{C 3}=0.155 \times d g
$$

Then the probability that the diameter dc will occur is:

$$
p_{i}=\frac{3!}{n_{g}!n_{m}!n_{k}!} p_{r_{d g}}^{n g} \times p_{r_{d m}}{ }^{n m} \times p_{r_{d k}}^{n k}
$$

The mean pore diameter $\mathrm{dc}_{\mathrm{m}}$ then calculated by the following equation:[32]

$$
d c_{m}=\sum_{i=1}^{n} p_{i} d c_{i}
$$

Fig. 2.9.1
General case

Fig. 2.9.3 pore by two Different spheres
Diameters ds $=\mathbf{d s}>\mathbf{d l}$

Fig. 2.9.2 pore by two different spheres Diameters $\mathbf{d g}=\mathbf{d g}>\mathbf{d k}$

Fig.2.9.4 pore by three equal spheres diameters

The calculation of the pore diameter (dc) is based on the distribution of the four sizes of spheres and according to their arrangement the equations in above. The calculations of the probabilities are based on the number percent of each type of spheres and the other probabilities will be obtained from it as in the following equations:

- Probability due to length...[32]

$$
L=\left(d_{1} \times N_{1}\right)+\left(d_{2} \times N_{2}\right)+\left(d_{3} \times N_{3}\right)+\left(d_{4} \times N_{4}\right)
$$

$$
\begin{array}{ll}
L_{1}=\frac{\left(d_{1} \times N_{1}\right)}{L} & L_{2}=\frac{\left(d_{2} \times N_{2}\right)}{L} \\
L_{3}=\frac{\left(d_{3} \times N_{3}\right)}{L} & L_{4}=\frac{\left(d_{4} \times N_{4}\right)}{L}
\end{array}
$$

- Probability due to area...[32]

$$
A=\left(d_{1}^{2} \times N_{1}\right)+\left(d_{2}^{2} \times N_{2}\right)+\left(d_{3}^{2} \times N_{3}\right)+\left(d_{4}^{2} \times N_{4}\right)
$$

$$
\begin{array}{ll}
A_{1}=\frac{\left(d_{1}^{2} \times N_{1}\right)}{A} & A_{2}=\frac{\left(d_{2}^{2} \times N_{2}\right)}{A} \\
A_{3}=\frac{\left(d_{3}^{2} \times N_{3}\right)}{A} & A_{4}=\frac{\left(d_{4}^{2} \times N_{4}\right)}{A}
\end{array}
$$

- Probability due to volume...[32]

$$
\begin{align*}
& V=\left(d_{1}^{3} \times N_{1}\right)+\left(d_{2}^{3} \times N_{2}\right)+\left(d_{3}^{3} \times N_{3}\right)+\left(d_{4}^{3} \times N_{4}\right) \\
& V_{1}=\frac{\left(d_{1}^{3} \times N_{1}\right)}{V} V_{2}=\frac{\left(d_{2}^{3} \times N_{2}\right)}{V} \\
& V_{3}=\frac{\left(d_{3}^{3} \times N_{3}\right)}{V} V_{4}=\frac{\left(d_{4}^{3} \times N_{4}\right)}{V}
\end{align*}
$$

The diameters used in the calculations of the pore diameter (dc) are:
D1 $=10.6 \mathrm{~mm}$.
D2 $=14.97 \mathrm{~mm}$.
D3 $=20.89 \mathrm{~mm}$.
D4 $=\mathbf{2 5 . 8 4 m m}$.

# Chapter Three <br> <br> Experimental Work 

 <br> <br> Experimental Work}

### 3.1 Materials and Tools

The experimental work was done by using the main system which is consists of many instruments:-

1. Graduated glass cylinder with height 16.5 cm , diameter 13 cm , knowing that this cylinder is opened from the top and bottom.
2. The sieve, which represents the filter plate, that the cylinder will be put on it.

This sieve is used to retain the spheres that the packed bed consist of, and has square pores with diameters $1.1 * 1.1 \mathrm{~cm}$.It is connected to the cylinder by a resin material mixed with black cascade maker. This system and its parts are shown in the Fig.3.1.
3. A digital balance (for high accuracy) was used to weight the mass of the input and output material from the packed bed.
4. Four sizes of glass spheres were used as the packed beds. Details of these spheres are given in Table 3.1.

Table 3.1 Diameters of glass spheres

| Diameter (mm) | symbol |
| :---: | :---: |
| 10.6 | 1 |
| 14.97 | 2 |
| 20.89 | 3 |
| 25.84 | 4 |

5. To represent the impurities separated by the packed bed, many types of spheres were used. These impurities are listed with their diameter and weight in Table 3.2.

Table 3.2 impurities weights and diameters

| Diameter of impurities <br> $(\mathrm{mm})$ | Symbol of <br> mixture | Weight (gm) | Number of <br> impurities |
| :---: | :---: | :---: | :---: |
| $1.2-3.3$ | (glass) | A | 50 |
| 4.2 | (lead) | B | 60 |
| 6 | (lead) | C | 24.7 |

In each experiment, the spheres are mixed in a certain number of layers to make the packed bed, and the impurities of different diameters are used in the packed bed to measure the percent output of each case. Details are listed in the next section.

### 3.2 Steps of Experiments

The packed bed were made is consists of four sizes of glass spheres with diameters $10.6,14.97,20.89$ and 25.84 mm .in each experiments a certain quantity of the four sizes of spheres and number percent were taken.

In each experiment, different numbers of layers (four, five, and six layers) were used. The following steps were taken in each experiment, and are listed as follows:-

1. The number percent of the four sizes of glass spheres were chosen.
2. A certain number of each type of the glass spheres are taken to make the first layer in the packed bed and this mixture is put inside the cylinder. This mixture has the same number percent that is chosen as in step 1.
3. The other layers are made and put it inside the cylinder to make the packed bed .the variable value in each experiments is the number percent of the mixture.
4. After the packed bed is completed inside the cylinder, the system is being ready to start, and entering a certain weight of the impurities and we start with group A from the top of the cylinder and by using the air of the compressor for 3 min . to reach the steady state, then the output of the impurities taken and weigh it by using the digital balance. And the procedure is repeated for mixtures B and C .
5. The above four steps are repeated for five and six layers of the packed beds with the same weight of impurities.

## Chapter Four

## Results and Discussion

### 4.1 Introduction

In this section, the results of the calculation in the previous chapters will be applied for the four types of the packed bed.

Many experiments were done for the same number, composition, size, and diameters of the packed bed and impurities were used in chapter three.

Figures from 4.1 to 4.10 show the relationship between the probability and the diameter of the pores $\left(\mathrm{d}_{\mathrm{c}}\right)$ for each distribution, and show the difference between the distributions of each case and this is the theoretical part.

The results of experimental and theoretical method will be related in a way that we can conclude relations between the mean pore diameter $\left(\mathrm{d}_{\mathrm{cm}}\right)$ and percent output of impurities, also a relation between the number of layers and percent output and size of impurities and percent output.

### 4.2 Particle Separation

The experimental results for four, five, and six layers are given below, and ten experiments are done in each layer.

## - Experiment 1:

- Number of spheres of group $1=11$
- Number of spheres of group $2=11$
- Number of spheres of group $3=11$
- Number of spheres of group $4=11$

$$
\mathrm{N} 1=0.25, \mathrm{~N} 2=0.25, \mathrm{~N} 3=0.25, \mathrm{~N} 4=0.25
$$

Table 4.1 Results of Experiment 1

| Size of impurities (mm) | Weight of spheres <br> (input )(gm) | Weight of spheres output (gm) <br> four layers <br> five layers <br> six layers |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $1.2-3.3$ | 50 | 47 | 45.8 | 44.2 |  |  |  |  |
| 4.2 | 60 | 22 | 20 | 14.5 |  |  |  |  |
| 6 | 24.7 | 16.9 | 11.2 | 7.5 |  |  |  |  |
| height of the bed (cm) |  |  |  |  |  | 9 | 11 | 15 |

| $\begin{array}{c}\text { Percent output (wt. \%) } \\ \text { four layers } \\ \text { five layers }\end{array}$ |  |  |
| :---: | :---: | :---: |
| six layers |  |  |$]$| 94 | 91.6 |
| :---: | :---: |
| 36.67 | 33.3 |
| 68.4 | 45.3 |

## - Experiment 2:

- Number of spheres of group $1=9$
- Number of spheres of group $2=13$
- Number of spheres of group $3=18$
- Number of spheres of group $4=5$

$$
\mathrm{N} 1=0.2, \mathrm{~N} 2=0.3, \mathrm{~N} 3=0.4, \mathrm{~N} 4=0.1
$$

Table 4.2 Results of experiment 2

| Size of impurities (mm) | Weight of spheres <br> (input )(gm) | Weight of spheres output (gm) <br> four layers <br> five layers |  |  |
| :---: | :---: | :---: | :---: | :---: |
|  | six layers |  |  |  |$|$| $1.2-3.3$ | 50 | 46.6 | 44.8 | 40.6 |  |  |  |  |

$$

### 4.4. Relationships between Mean Pore Diameter and Percent output of Impurities

The constant parameters in this work are the diameters of the packed bed .as shown in the first chapters of this research, these diameters are 10.6, 14.97, 20.89, and 25.84 mm respectively.

The number percent distribution is the start point, because the composition of the packed bed in the experimental work depends on the number percent, then the conversion to the other distribution, which is due to length, area, and volume will be made with their relations and percent output of impurities.

The mean pore diameter due to number, length, area, and volume will be related with three types of impurities that passes through the packed bed layers and these types of impurities are:

1. spheres of $1.2-3.3 \mathrm{~mm}$
2. spheres of 4.2 mm
3. spheres of 6 mm

The mean pore size and the weight percent of impurities will be related in this section for each packed bed made four sizes of spheres. In spite of the variety of the composition of different packing, the mean pore size is the same calculated.

The figures from (4.11) to (4.13) show the relationship between the mean pore diameter $\left(\mathrm{dc}_{\mathrm{m}}\right)$ due to number with percent output of impurities for four, five, and six layers.

The reason of the distribution points from fig.4.11 to 4.13 was because the mean pore diameter was selected randomly not under specific rules.

The figures from (4.11) to (4.13) show the proportionality between the mean pore diameter and the percent output for number percent distribution for four, five, and six layers and they are proportional to each other, and these figures show intersection points in 4.2 mm and 6 mm for four and five layers because the percent output was sometimes the same.

Figures from 4.14-4.22 show the distribution points because the mean pore diameter was taken for different assumed distribution not under specific rules.

From the above relations it is clear that the curve of the small mixture has higher values of percent output (e.g. the curve of 1.2-3.3 mm mixture) and the curve of the large diameter of impurities has smaller values of percent output for the three layers.

Fig. 4.11 Mean pore diameter due to number vs. percent output (four layers)

Fig. 4.12 Mean pore diameter due to number vs. percent output (five layers)

Fig. 4.21 Mean pore diameter due to volume vs. percent output (five layers)

Fig. 4.22 Mean pore diameter due to volume vs. percent output (six layers)

### 4.5 Relation between Size of Impurities and Percent Output of Impurities

Figures from (4.23) to (4.32) represent this relation and three sizes of impurities are taken and percent outputs of impurities are taken from the experimental work results.

It is clear that the curves in the figures below for four, five, and six layers shows that the percent output of impurities decreasing with increasing the size of impurities and this is clear in the first two points of each curve. But in size 6 mm points for the three curves in figures $5.23,5.24,5.25$, and 5.27 the percent output of impurities will increase with decreasing the size of
impurities and this make sure that the exist of bigger pores than the theoretical maximum pores, but the effect of these pores is reduce and disappear when increasing the number of layers, and the number of available pores for passing the first particle, which has volume of 6 mm and that will be more than the available particles for the smaller particles and that leading to increase the probability of configuration the bridge between the little particles and that will prohibit the little particles from passing through a good pores for passing particles as a speed not a pile.

Fig. 4.23 size of impurities vs. percent output for: $\mathrm{N} 1=0.25, \mathrm{~N} 2=0.25, \mathrm{~N} 3=0.25, \mathrm{~N} 4=0.25$

Fig. 4.24 size of impurities vs. percent output for: $\mathrm{N} 1=0.2, \mathrm{~N} 2=0.3, \mathrm{~N} 3=0.4, \mathrm{~N} 4=0.1$

Fig. 4.25 size of impurities vs. percent output for: $\mathrm{N} 1=0.42, \mathrm{~N} 2=0.25, \mathrm{~N} 3=0.18, \mathrm{~N} 4=0.15$

Fig. 4.26 size of impurities vs. percent output for: $\mathrm{N} 1=0.5, \mathrm{~N} 2=0.34, \mathrm{~N} 3=0.1, \mathrm{~N} 4=0.06$

Fig. 4.27 size of impurities vs. percent output for: $\mathrm{N} 1=0.38, \mathrm{~N} 2=0.29, \mathrm{~N} 3=0.13, \mathrm{~N} 4=0.2$

Fig. 4.28 size of impurities vs. percent output for: $\mathrm{N} 1=0.3, \mathrm{~N} 2=0.2, \mathrm{~N} 3=0.3, \mathrm{~N} 4=0.2$

Fig. 4.29 size of impurities vs. percent output for: $\mathrm{N} 1=0.25, \mathrm{~N} 2=0.35, \mathrm{~N} 3=0.15, \mathrm{~N} 4=0.25$

Fig. 4.30 size of impurities vs. percent output for: $\mathrm{N} 1=0.6, \mathrm{~N} 2=0.18, \mathrm{~N} 3=0.18, \mathrm{~N} 4=0.03$

Fig. 4.31 size of impurities vs. percent output for:
$\mathrm{N} 1=0.23, \mathrm{~N} 2=0.07, \mathrm{~N} 3=0.35, \mathrm{~N} 4=0.35$

Fig. 4.32 size of impurities vs. percent output for: $\mathrm{N} 1=0.8, \mathrm{~N} 2=0.04, \mathrm{~N} 3=0.13, \mathrm{~N} 4=0.03$

### 4.6 Relation between Number of Layers and Percent Output of Impurities

In this relation, the variety of the curves can be seen widely; figures from (4.33) to (4.42) represent this relation and each curve represents the size of impurities for four, five, and six layers. The proportionality between the size of impurities and percent output is inversely.

Figure 4.33 shows that the smaller size of impurities (1.2-3.3 mm) has the higher value of percent output because the diameter of the pores for the packed bed larger than the diameter of the impurities so, the weight of this
type of impurities that leaves the packed bed is very closely to the input weight.

The third curve of impurities ( 6 mm ) has smaller value of percent output. The variety in the shape of the curves is coming from the variety of the composition of the spheres in the packed bed as shown in figures below.

Fig. 4.33 number of layers vs. percent output for: $\mathrm{N} 1=0.25, \mathrm{~N} 2=0.25, \mathrm{~N} 3=0.25, \mathrm{~N} 4=0.25$

Fig. 4.34 number of layers vs. percent output for:
$\mathrm{N} 1=0.2, \mathrm{~N} 2=0.3, \mathrm{~N} 3=0.4, \mathrm{~N} 4=0.1$

Fig. 4.35 number of layers vs. percent output for: $\mathrm{N} 1=0.42, \mathrm{~N} 2=0.25, \mathrm{~N} 3=0.18, \mathrm{~N} 4=0.15$

Fig. 4.36 number of layers vs. percent output for: $\mathrm{N} 1=0.5, \mathrm{~N} 2=0.34, \mathrm{~N} 3=0.1, \mathrm{~N} 4=0.06$

Fig. 4.37 number of layers vs. percent output for: $\mathrm{N} 1=0.38, \mathrm{~N} 2=0.29, \mathrm{~N} 3=0.13, \mathrm{~N} 4=0.2$

Fig. 4.38 number of layers vs. percent output for:

$$
\mathrm{N} 1=0.3, \mathrm{~N} 2=0.2, \mathrm{~N} 3=0.3, \mathrm{~N} 4=0.2
$$

Fig. 4.39 number of layers vs. percent output for:
$\mathrm{N} 1=0.25, \mathrm{~N} 2=0.35, \mathrm{~N} 3=0.15, \mathrm{~N} 4=0.25$

Fig. 4.40 number of layers vs. percent output for: $\mathrm{N} 1=0.6, \mathrm{~N} 2=0.18, \mathrm{~N} 3=0.18, \mathrm{~N} 4=0.03$

Fig. 4.41 number of layers vs. percent output for: $\mathrm{N} 1=0.23, \mathrm{~N} 2=0.07, \mathrm{~N} 3=0.35, \mathrm{~N} 4=0.35$

Fig. 4.42 number of layers vs. percent output for: $\mathrm{N} 1=0.8, \mathrm{~N} 2=0.04, \mathrm{~N} 3=0.13, \mathrm{~N} 4=0.03$

## Chapter Five

## Conclusions and Recommendations For Future Work

### 5.1. Conclusions

1. From the theoretical part of this research, it was concluded that the probability of finding pore size in any packed bed is different for each kind of distribution.
2. the percent output of impurities, which passed through the packed bed decrease with increasing the number of layers; and also decrease with increasing the size of impurities ;but in case of 6 mm impurities it is increase not like the other cases and this make sure that the exist of bigger pores than the theoretical maximum pores, but the effect of these pores is reduce and disappear when increasing the number of layers, and the number of available pores for passing the first particle, which has volume of 6 mm and that will be more than the available particles for the smaller particles and that leading to increase the probability of configuration the bridge between the little particles and that will prohibit the little particles from passing through a good pores for passing particles as a speed not a pile.
3. Increasing the number of large spheres in the packed bed leads to increase the percent output of impurities and this in turn leads to increase the mean pore diameter (due to number, length, surface area, and volume), and
increase the number of small or medium spheres leads to a reduction in the output of impurities and reduction in the mean pore diameter.

### 5.2. Recommendation for Future Work

1. Developing equations that give the relation between the probability and the diameter of the pores $\left(d_{C}\right)$ for define types of distribution (RRSB, normal distribution).
2. Taking other types of packing and impurities with different composition, diameters, and layers to study the properties of the packing.
3. Choosing the distribution for the types of spheres which are used in the packing to increase the accuracy and this is achieved by using equations or graphs, and this kind of distribution helps to know best kinds of impurities that may be used to pass through the packing.

## Appendix A

## Sample of calculation

As example for case of:

$$
\mathrm{d}_{\mathrm{K}}=10.6 \mathrm{~mm} \quad \mathrm{~d}_{\mathrm{M}}=14.97 \mathrm{~mm} \quad \mathrm{~d}_{\mathrm{G}}=20.89 \mathrm{~mm}
$$

And:

$$
\mathrm{N}_{\mathrm{K}}=0.20 \quad \mathrm{~N}_{\mathrm{M}}=0.30 \quad \mathrm{~N}_{\mathrm{G}}=0.40
$$

Diameter of the pores for three different sizes of spheres:

$$
\begin{equation*}
d_{C 3}=\frac{K_{4}-\left(K_{4}^{2}-4 K_{5}\right)^{0.5}}{2} * d_{g} \tag{2.1}
\end{equation*}
$$

Where:

$$
\begin{aligned}
& k_{1}=\left[\frac{\left(a_{m}+1\right)}{\left(a_{m}-1\right)}\right]^{2} \quad k_{2}=\frac{4 a_{m}}{\left(a_{m}+1\right)} \\
& k_{3}=\left(a_{k}^{2}+a_{k} k_{2}\right)^{0.5}-a_{k} \quad k_{4}=\left(k_{2}+2 k_{3}\right) * k_{1} \\
& k_{5}=k_{3}^{2} * k_{1} \\
& a_{k}=\frac{d_{k}}{d_{g}} \ldots \ldots \ldots . .(<=1)
\end{aligned}
$$

$\mathrm{a}_{\mathrm{M}}=14.97 / 20.89=0.7166$
$\mathrm{a}_{\mathrm{K}}=10.6 / 20.89=0.5074$
$\mathrm{K}_{1}=[(0.7166+1) /(0.7166-1)]^{2}=36.6892$
$\mathrm{K}_{2}=4 * 0.7166 /(0.7166+1)=1.6698$
$\mathrm{K}_{3}=\left(0.5074^{2}+\left(0.5074^{*} 1.6698\right)\right)^{0.5}-0.5074=0.5436$
$\mathrm{K}_{4}=(1.6698+(2 * 0.5436)) * 36.6892=101.1521$
$\mathrm{K} 5=0.5436^{2} * 36.6892=10.8417$
$d_{c 3}=\left[\frac{101.1521-\left(101.1521^{2}-4 * 10.8417\right)^{0.5}}{2}\right] * 20.89$
$=2.2414 \mathrm{~mm}$.
$p_{i}=\frac{3!}{n_{g}!n_{m}!n_{k}!} p_{r_{r_{k}}}{ }^{n g} * p_{r_{r a m_{m}}}{ }^{n m} * p_{r_{r_{k}}}{ }^{n k}$

Where $\mathrm{r}_{\mathrm{g}}+\mathrm{r}_{\mathrm{m}}+\mathrm{r}_{\mathrm{k}}=3$
$\mathrm{N}_{\mathrm{k}}=1$
$\mathrm{N}_{\mathrm{m}}=1$
$\mathrm{N}_{\mathrm{g}}=1$

$$
\begin{aligned}
p_{3} & =\frac{1 * 2 * 3}{1 * 1 * 1} *\left[(0.4)^{1} *(0.3)^{1} *(0.2)^{1}\right. \\
& =0.144
\end{aligned}
$$

To calculate the mean pore diameter $\left(\mathrm{dc}_{\mathrm{m}}\right)$ for packed bed consisting of the above number percent of sphere, using the following equation:

$$
d c_{m}=\sum_{i=1}^{n} p_{i} d c_{i}
$$

$\mathrm{d}_{\mathrm{Cm}}=1.643 * 0.015625+1.822281 * 0.046875+1.982672 * 0.046875+2.044092$ *0.046875 $+2.074898 * 0.046875+2.241816 * 0.09375+2.32035 * 0.015625$
$+2.356291 * 0.09375+2.481983 * 0.046875+2.564951 * 0.046875+2.623555 *$
$0.09375+2.71303 * 0.046875+2.7828 * 0.046875+2.865761 * 0.046875+3.048275 *$ $0.09375+3.23795 * 0.015625+3.251875 * 0.046875+3.456442 * 0.046875+$ $3.710169 * 0.046875+4.0052 * 0.015625$.

$$
=2.626234 \text {. }
$$

## الخلاصة

تستحدم الحشوات في عدة عمليت صناعية (امتصاص، امدصاص، تقطير، ترشيح). يتضمن هذا

الجاتب النظري المعطى من قبل (latif) يتضمن ايجاد قطر الفتحة، معدل قطر الفتحة، الاحتمالية، و اوجدت النتـائج باستخدام برامج الحاسوب (QBASIC, EXCEL) و اوجدت النتائج ان الاحتمالية تختلف لكل احتمالية.

الجاتب العملي يتضمن عمل حشوة ذات تراكيب و طبقات مختلفة و لكن نفس الاقطار المستخدمة في الجاتب النظري و وزن الشوائب قبل امرار ها على الحشوة و بعد خروجها منها لايجـاد النسبة
 اوجدت النتائج المحسوبة من الجانب العملي ان النسبة المئوية للشو ائب تقل بزيادة عدد الطبقـات و ايضا تقل بزيادة حجم الشوائب.

## شكر و تقدير

اودُ أن أعبر عن خـالص شكري وتقديرِي وَ امتنـاني العميق للمشـرف الـككتور محمـ نصـيف لطيف لمــا بذلـه مـن جهد كبيـر و ارشـادات سـديدة و قيمـة طـو ال فتـرة اعداد الرسالة.

أودُ أيضــا أن أشـكر السـبد رئـيس القسـم و مـوظفي قــم الـهندسـة الكيماويـة لإبـدائهم المسـاعدة اللاز مة أثناء فترة البحث.

و لا أنسىى أن أنقدم بالثككر و الامتنان إلى من لازمني طو ال فترة البحث وخلال أصـعب الظـروف إلى أعز مـن في الوجود إلـى أبـي و أمـي و جميع أفراد عـائلتي فلهم جزيـل الثنكر و النقدير.

م..يسرى صـابر كريم
(يجاد حجم الفتحة في حشوة مكونة من
اربعة حجوم من الكرات الزجاجية

رسالة
مقـمة الى كلية الهنسسة في جامعة النهرين و هي جزء من متطلبات نيل درجة ماجستير علوم في الهندسة الكيمياوية

من قبل
يسرى صابر كريم
